ABSTRACT

This paper presents a method for gradient-based shape optimization using unsteady models of turbulent flowfields, for which forward simulations are already expensive and adjoint calculations diverge or require costly regularization. The proposed method targets an objective and constraints computed from the time-averaged flowfield and does not use either an unsteady adjoint nor an input-to-output surrogate. The method relies on the field-inversion, machine-learning (FIML) approach, in which a correction field modifies the production term in a Reynolds-averaged Navier-Stokes (RANS) model of the flow. Steady, adjoint-based, field inversion yields this correction field, and a neural-network model is trained, only from readily-available unsteady primal data, to reproduce the field from local flow quantities. Gradient-based shape optimization is then performed using the corrected RANS model, which must include a linearization of the correction field calculation for accurate gradients. The complete design optimization loop consists of iterations of unsteady simulation, FIML, and steady adjoint-based optimization. Low and moderate Reynolds number airfoil optimization problems demonstrate the performance of the proposed method, and comparisons to RANS-alone designs illustrate the importance of accounting for the unsteady flow effects in the optimization.

1. Introduction

Turbulent flows exist in many fluid systems, including in the aerodynamics of aerospace vehicles. Many techniques have been developed to simulate such flows, ranging from completely ignoring viscous effects, for example through potential-flow or Euler equations, to resolving every turbulent scale via direct numerical simulation (DNS). In between lie steady-state methods based on Reynolds averaging (RANS), and unsteady methods such as large-eddy and detached-eddy simulations (LES, DES). Whereas steady-state methods are generally adequate for vehicles at on-design conditions, high-fidelity simulations at off-design conditions, often characterized by regions of separated flow, generally require unsteady methods. This latter class of flows provides the setting for the present work, which addresses the design of aerodynamic shapes at off-design conditions.

Unsteady models of turbulent flow complicate shape optimization in at least two ways. First, the simulations are much more expensive than steady models, so that each function evaluation, usually a statistic such as a time-averaged scalar output of interest, requires orders of magnitude more computational time and resources. This limits the applicability of many-query studies, such as optimization, particularly gradient-free methods that rely on numerous function evaluations [1]. Second, the chaotic nature of unsteady turbulent simulations prevents the application of linear sensitivity techniques for evaluation of gradients. In particular, adjoint methods, the hallmark of shape optimization [2–6], cannot be directly applied, except in special cases such as quasi-periodic flows [7], as the unsteady adjoint equations are unstable in such systems [8] and require expensive regularization techniques to provide meaningful answers [9–14]. Furthermore, unsteady adjoints come with massive storage and computation requirements that become impractical for forward simulations, which already stress computational resources [15]. For these two reasons, the present work does not use unsteady adjoint methods.

Unsteady adjoints are useful when computing sensitivities of deterministic events, such as maneuvers, gust interactions, or short-duration aeroelastic events [16-24]. However, for turbulent flows, they provide perhaps too much information: the sensitivity of an output to a flow residual at a single point in space and time loses significance when that particular state may not appear in another simulation

that follows a different trajectory due the chaotic nature of the flow [25]. In such systems, of engineering interest are generally statistical quantities, such as time averages of outputs, and if a steady-state model were able to yield these quantities with sufficient accuracy, it would be much more amenable to gradient-based optimization.

Many steady-state turbulence models exist, most based on Reynolds averaging of the Navier-Stokes equations. However, as discussed previously, these models often do not provide sufficient accuracy relative to unsteady models at off-design conditions. Indeed, the creation of a general turbulence model that is accurate across multiple flow regimes continues to be an elusive quest [26]. Presently, we forego generality and create multiple steady-state models, each specific to the unsteady case being considered. We only use the model to enable an efficient calculation of the derivatives required for optimization, instead of trying to apply the model to vastly different flow regimes.

The turbulence modeling approach we take here is based on the idea of field inversion and machine learning (FIML) [27–33]. The idea of FIML is to start with an existing steady-state model and to correct it via a PDE-level correction factor on one or more of the turbulence modeling terms. The unsteady simulation, here in lieu of experimental or other external data, provides the truth solution for the inverse problem for this correction factor, and a machine-learning approach maps local flow features to the correction factor. The result is a corrected steady-state model that can be used on different meshes or shapes. Whereas previous works have used FIML as a general turbulence modeling strategy with mixed generalizability success [26], in this work we only rely on FIML's local accuracy, at/near the conditions for which it was trained. This relaxation of expectations then simplifies aspects of the FIML approach, particularly the amount of training data, size of the machine learning neural network, and the generality of the inputs.

We stress that the use of machine learning in this work is not to create a direct input-to-output surrogate of the high-fidelity model, as has been done in many previous works [34–37]. Instead, machine learning is only used to provide a correction to what is already a high-fidelity model, RANS, so as to make it better represent an even higher-fidelity model, unsteady turbulence. The corrected RANS model enables calculation of the objective gradient, which is needed for gradient-based shape optimization.

The proposed unsteady optimization approach consists of iterative turbulence model calibration, through FIML and a *limited* number of unsteady simulations, coupled with steady-state optimization using the corrected turbulence models. The number of unsteady simulations required is much lower than the function evaluations demanded by any gradient-free or even gradient-based method, since the optimization is offloaded to the steady-state model. The unsteady simulations only provide model training data, and as the model is often accurate in the vicinity of training, only a few unsteady evaluations (2-4 in the present results) are typically required. However, as will be shown in the results, the accuracy improvements of the corrected model can make a difference in the optimized shapes, particularly in cases where the uncorrected model loses applicability.

The outline for the remainder of this paper is as follows. Section 2 presents the numerical approach used in this work, a discontinuous finite-element discretization for both the primal and adjoint problems. Section 3 presents the design parametrization for airfoil shapes, and the gradient-based optimization method. Sections 4 and 5 discuss the field-inversion and machine learning approaches, which are used in the unsteady optimization approach that is summarized in Section 6. Finally, Section 7 presents results of several unsteady airfoil optimizations, and Section 8 concludes with a summary and a discussion of future directions.

2. Discretization

2.1. Governing equations

We consider a system of unsteady partial differential equations in conservative form,

$$\frac{\partial \mathbf{u}}{\partial t} + \nabla \cdot \vec{\mathbf{F}}(\mathbf{u}, \nabla \mathbf{u}) + \mathbf{S}(\mathbf{u}, \nabla \mathbf{u}) = \mathbf{0},\tag{1}$$

where $\mathbf{u} \in \mathbb{R}^s$ is the s-component state vector, $\tilde{\mathbf{F}} \in \mathbb{R}^{\dim \times s}$ is the flux vector, dim is the spatial dimension, and $\mathbf{S} \in \mathbb{R}^s$ is the source term arising from the turbulence model, in this work the Reynolds-averaged Navier-Stokes (RANS) equations with the Spalart-Allmaras (SA) closure [38,39]. A detailed exposition of the equations and closure relations of the model as used presently can be found in previous work [40,39,41], which also includes code verification results. The choice of the SA model is driven by its robustness, simplicity, and the target application of external aerodynamic flows. The same strategy of a dynamic correction could be applied to other turbulence models, some of which may be more appropriate to particular applications, such as internal flows or bluff bodies.

Relevant to this study is the eddy viscosity equation, which contains the turbulence production term that will be modified through a multiplicative correction factor, β ,

$$\frac{\partial(\rho\tilde{\nu})}{\partial t} + \nabla \cdot (\rho\vec{\nu}\tilde{\nu}) - \frac{1}{\sigma}\nabla \cdot [\rho(\nu + \tilde{\nu}f_n)\nabla\tilde{\nu}] = -\frac{1}{\sigma}(\nu + \tilde{\nu}f_n)\nabla\rho \cdot \nabla\tilde{\nu} + \frac{c_{b2}}{\sigma}\rho\nabla\tilde{\nu} \cdot \nabla\tilde{\nu} + [\beta]P - D. \tag{2}$$

In this equation, ρ is the density, \vec{v} is the velocity, \vec{v} turbulence working variable, f_n is a function that is active for $\vec{v} < 0$, c_{b2} , σ are model constants, P is the turbulence production function, and D is the turbulence destruction function. Scaling P by β affects the entire solution as the eddy viscosity equation is coupled to the conservation equations.

The SA model uses the distance, d, to the closest wall in several closure relations. Modifications to d, usually in the form of limits on its maximum value, yield models for unsteady, detached-eddy simulations (DES) [42]. In the present work, we implement a very simple DES model for unsteady high-Reynolds number simulations,

$$d = d_{\text{max}} \tanh(d/d_{\text{max}}),\tag{3}$$

where $d_{\rm max}$ is a prescribed distance, set to 2% of the chord length for airfoil simulations. In contrast to most DES models, which relate the limits on d to the mesh size, this choice eliminates complications of grid size effects on the unsteady solution. Moreover, we are not overly concerned with the model accuracy, as our simulations are at present two-dimensional. Instead, the simple DES model brings in unsteadiness that is representative of the manner in which actual three-dimensional DES models yield chaotic flow or limit-cycle oscillations that preclude an unsteady adjoint solution for optimization. For the purpose of optimization, we assume that the simple-model DES solutions are higher-fidelity than the steady RANS solutions.

2.2. The discontinuous Galerkin method

The unsteady optimization strategy presented in this work is not specific to the spatial or temporal discretization. For the results, we use a discontinuous Galerkin (DG) finite-element spatial discretization [43–46], with the Roe [47] convective flux and the second form of Bassi and Rebay (BR2) [48] for the viscous treatment. The state is approximated on an unstructured mesh of non-overlapping elements using polynomials of order p. Following a finite-element weak formulation and a choice of polynomial basis, the semi-discretized form of the equations is

$$\mathbf{M}\frac{d\mathbf{U}}{dt} + \mathbf{R}(\mathbf{U}) = \mathbf{0},\tag{4}$$

where $\mathbf{U} \in \mathbb{R}^N$ is the discrete state vector, N is the total number of unknowns, $\mathbf{R}(\cdot) \in \mathbb{R}^N$ is the nonlinear spatial residual, and $\mathbf{M} \in \mathbb{R}^{N \times N}$ is the block-element sparse mass matrix. For steady simulations, the time derivative term drops out, although pseudo-time continuation remains in the solver to drive the steady residual to the convergence criterion [49], which is an L_1 norm drop of eight orders of magnitude. The solver consists of a Newton-Raphson method with the generalized minimum residual (GMRES) [50] linear solver, preconditioned by an element-line Jacobi smoother with a coarse-level (p = 1) correction [45,51]. For unsteady simulations, we use a third-order modified extended backward difference formula [52] applied to the semi-discrete form.

2.3. The discrete adjoint

For a scalar output computed from the state vector, $J(\mathbf{U})$, the discrete steady adjoint vector, $\Psi \in \mathbb{R}^N$, is the local sensitivity of J to perturbations in the steady residual, \mathbf{R} [53]. Linearization of the residual and output shows that the adjoint satisfies the following linear equation,

$$\left(\frac{\partial \mathbf{R}}{\partial \mathbf{U}}\right)^T \mathbf{\Psi} + \left(\frac{\partial J}{\partial \mathbf{U}}\right)^T = \mathbf{0}. \tag{5}$$

This equation is solved using the same preconditioned GMRES method used in the primal solver. The adjoint vector can be used to efficiently compute PDE-constrained sensitivities of the output with respect to parameters, \mathbf{x} , of the problem. In general, if both the residuals and the output depend on \mathbf{x} , the PDE-constrained sensitivity of the output with respect to the parameter vector is

$$\frac{dJ}{d\mathbf{x}} = \frac{\partial J}{\partial \mathbf{x}} + \mathbf{\Psi}^T \frac{\partial \mathbf{R}}{\partial \mathbf{x}}.$$
 (6)

In this work, \mathbf{x} consists of shape and operational parameters, and derivatives of J and \mathbf{R} with respect to \mathbf{x} are evaluated using finite-differences. This poses no computational bottleneck in the present study with a small number of parameters. For larger numbers of parameters, analytical or algorithmic differentiation methods can be applied to increase the efficiency of this calculation.

3. Design optimization

We consider trimmed optimization problems, in which we distinguish between shape design parameters, $\mathbf{x}^{\text{des}} \in \mathbb{R}^{n_{\text{des}}}$, and trim parameters, $\mathbf{x}^{\text{trim}} \in \mathbb{R}^{n_{\text{trim}}}$, concatenated into $\mathbf{x} = [\mathbf{x}^{\text{des}}; \mathbf{x}^{\text{trim}}] \in \mathbb{R}^{n_{\text{par}}}$. Formulated as a minimization statement for a scalar output J, the problem reads

$$\min_{\mathbf{x}^{\text{des}}} \quad J(\mathbf{U}, \mathbf{x})
\text{s.t.} \quad \mathbf{R}(\mathbf{U}, \mathbf{x}) = \mathbf{0}
\mathbf{R}^{\text{trim}} \equiv \mathbf{I}^{\text{trim}}(\mathbf{U}, \mathbf{x}) - \bar{\mathbf{I}}^{\text{trim}} = \mathbf{0}$$
(7)

where $\mathbf{J}^{\text{trim}} \in \mathbb{R}^{n_{\text{trim}}}$ is the vector of trim outputs, and $\bar{\mathbf{J}}^{\text{trim}} \in \mathbb{R}^{n_{\text{trim}}}$ is the vector of target trim values. In this work, we consider $n_{\text{trim}} = 1$: the lift coefficient, c_{ℓ} , trimmed by angle of attack, α .

3.1. Shape optimization with concurrent trimming

To optimize the design, we use a gradient-based method: the Broyden-Fletcher-Goldfarb-Shanno (BFGS) [54] algorithm with a back-tracking line search. A notable feature of the implementation is concurrent trimming and optimization with a constrained gradient calculation. A given initial design, $\mathbf{x}_0^{\text{des}}$, is first trimmed using multiple solver iterations, where at each iteration the trim parameters are updated according to [55]

$$\mathbf{x}_{k+1}^{\text{trim}} = \mathbf{x}_{k}^{\text{trim}} + \Delta \mathbf{x}_{k}^{\text{trim}}, \qquad \Delta \mathbf{x}_{k}^{\text{trim}} = \left[\frac{d\mathbf{J}^{\text{trim}}}{d\mathbf{x}^{\text{trim}}} \right]_{k}^{-1} \left(\bar{\mathbf{J}}^{\text{trim}} - \mathbf{J}^{\text{trim}} (\mathbf{U}_{k}, \mathbf{x}_{k}) \right). \tag{8}$$

The PDE-constrained sensitivity matrix $\frac{d\mathbf{J}^{\text{trim}}}{d\mathbf{x}^{\text{trim}}} \in \mathbb{R}^{n_{\text{trim}} \times n_{\text{trim}}}$ is computed using adjoints of the trim outputs, and a user-specified trim tolerance, $\delta \mathbf{J}^{\text{trim}}$, serves as the termination criterion.

Following the initial trim, the shape optimization begins. Each design evaluation consists of a forward solution for the state \mathbf{U}_k , and adjoint solutions for the objective, J, and trim, \mathbf{J}^{trim} , outputs. The adjoints yield PDE-constrained sensitivities of all outputs with respect to the design and trim parameters. The trimmed gradient of the objective with respect to the design parameters is then

$$\frac{dJ}{d\mathbf{x}^{\text{des}}}\bigg|_{\text{trim}} = \frac{dJ}{d\mathbf{x}^{\text{des}}} + \frac{dJ}{d\mathbf{x}^{\text{trim}}} \frac{d\mathbf{x}^{\text{trim}}}{d\mathbf{x}^{\text{des}}}, \qquad \frac{d\mathbf{x}^{\text{trim}}}{d\mathbf{x}^{\text{des}}} = -\left[\frac{d\mathbf{J}^{\text{trim}}}{d\mathbf{x}^{\text{trim}}}\right]^{-1} \frac{d\mathbf{J}^{\text{trim}}}{d\mathbf{x}^{\text{des}}}, \tag{9}$$

where the expression for $\frac{d\mathbf{x}^{\text{trim}}}{d\mathbf{x}^{\text{des}}}$ follows from the requirement that changes in the design and trim parameters, $\delta \mathbf{x}$, must satisfy $\frac{d\mathbf{J}^{\text{trim}}}{d\mathbf{x}}\delta \mathbf{x} = \mathbf{0}$. The gradient of the objective output as given in (9) is then used in the BFGS algorithm.

3.2. Line search

During the BFGS line search, each objective function evaluation accounts for a linearized trim parameter change and includes an off-trim correction. Let $\bf p$ be the design-space search direction, and μ the current line-search step length. Prior to running the flow solver, the design and trim parameters are modified according to

$$\mathbf{x}^{\text{des}}(\mu) = \mathbf{x}_k^{\text{des}} + \Delta \mathbf{x}^{\text{des}}, \quad \Delta \mathbf{x}^{\text{des}} = \mu \mathbf{p}, \quad \mathbf{x}^{\text{trim}}(\mu) = \mathbf{x}_k^{\text{trim}} + \frac{d\mathbf{x}^{\text{trim}}}{d\mathbf{x}^{\text{des}}} \Delta \mathbf{x}^{\text{des}},$$
 (10)

where the purpose of the \mathbf{x}^{trim} modification is to maintain linearized trim conditions. The corresponding flow solution $\mathbf{U}(\mu)$ may not be exactly trimmed, as the state and outputs can be nonlinear, while the trim modification arises from linearizations about the zero step-length state and design. The objective calculation then includes an off-trim correction.

$$J(\mu) = J(\mathbf{U}(\mu), \mathbf{x}(\mu)) + \frac{dJ}{d\mathbf{x}^{\text{trim}}} \bigg|_{\mathbf{U}(\mu), \mathbf{x}(\mu)} \Delta \mathbf{x}^{\text{trim}}(\mu), \tag{11}$$

where the trim parameter change is computed from (8) using $\mathbf{U}(\mu)$, $\mathbf{x}(\mu)$.

The step length calculated from the line search, combined with the design-space search direction, determines the change in the design parameters. In addition, following the line search, the trim parameters are modified according to both (10), for the linear modification, and (8), for the nonlinear correction, with the latter using the trim sensitivity matrix already available from the last line-search iteration.

3.3. Airfoil parametrization

Many airfoil parametrizations have been developed for solving optimization problems [56,57], and in this work we only consider two simple approaches. The first is a continuous generalization of the 4-digit series from the National Advisory Committee for Aeronautics (NACA), modified for zero trailing-edge gap, in which the camber and thickness functions are

$$z_c(x) = \frac{z_{c,\text{max}}}{(1 - z_{c,\text{loc}})^2} \left[(1 - 2z_{c,\text{loc}}) + 2z_{c,\text{loc}}x - x^2 \right] (x < z_{c,\text{loc}}) + \frac{z_{c,\text{max}}}{z_{c,\text{loc}}^2} \left[2z_{c,\text{loc}}x - x^2 \right] (x \ge z_{c,\text{loc}}), \tag{12}$$

$$t(x) = t_{\text{max}} \left(0.2969 \sqrt{x} - 0.126x - 0.3516x^2 + 0.2843x^3 - 0.1036x^4 \right), \tag{13}$$

where $z_{c,\text{max}}$ is the maximum camber, the first NACA series digit divided by 100, $z_{c,\text{loc}}$ is the location of maximum camber, the second digit divided by 10, and t_{max} is the maximum thickness, the last two digits divided by 100. These expressions assume a unit chord airfoil with $0 \le x \le c = 1$. In the present study, we allow for continuous variation of the airfoil parameters.

The second parametrization allows for more flexibility in the camber and thickness profiles. It consists of polynomial expressions for both profiles, with bounding multiplicative envelopes,

$$z_c(x) = x(1-x) \left[c_0 + c_1 x + \ldots + c_{p_c} x^{p_c} \right], \tag{14}$$

$$t(x) = a \text{ abs}_{\text{smooth}} \left\{ \sqrt{x} (1 - x) \left[1 + t_1 x + \dots + t_{p_t} x^{p_t} \right], \ 0.2x (1 - x) \right\}$$
 (15)

where c_i are the coefficients of the order p_c camber polynomial, t_i are the coefficients of the order p_t thickness polynomial, and the smooth absolute value function is defined for positive b as

$$abs_{smooth}(a,b) = \begin{cases} |a| & \text{if } |a| \ge b\\ (a^2 + b^2)/(2b) & \text{otherwise} \end{cases}$$
 (16)

The coefficient a enforces a constant airfoil area, A,

$$\int_{0}^{1} t(x) dx = A. \tag{17}$$

3.4. Example steady optimization

To demonstrate the geometry parametrization and optimization algorithm, we consider the design of a minimum-drag airfoil at transonic cruise conditions, Mach number M = 0.8, Reynolds number $Re = 10^6$, and lift coefficient $c_\ell = 0.5$. Five parameters define the camber and four define the thickness, according to (14) and (15). The airfoil area is set to $A = 0.06c^2$. An initial symmetrical airfoil shape is constructed by setting all 9 camber/thickness parameters to 0. The computational mesh consists of 5390 quadrilaterals, curved to follow the geometry using an order q = 3 reference-to-global mapping. This airfoil is then trimmed to $c_\ell = 0.5$ using an adjoint-based process [55]

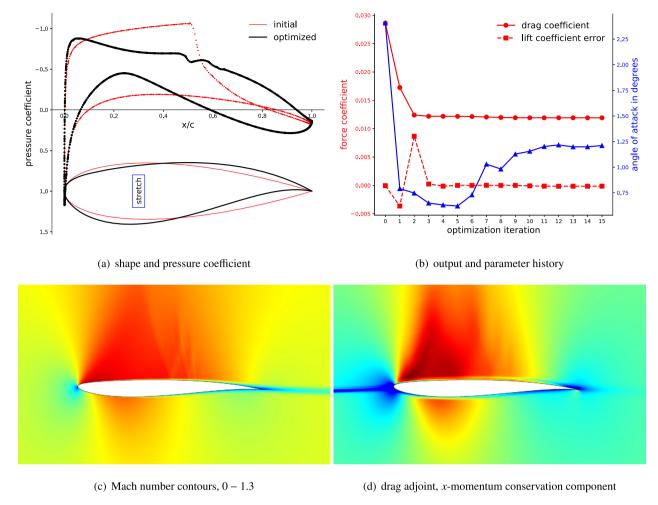

Fig. 1. Steady transonic airfoil shape optimization example: drag coefficient minimization at M = 0.8, $Re = 10^6$, $c_\ell = 0.5$. Field plots at optimized design.

with a pitch mesh deformation [20,55] creating the angle of attack change. Artificial-viscosity shock capturing [58] prevents spurious oscillations in the p=2 solution. The optimization then proceeds using the concurrent optimization and trimming algorithm described in Section 3.1.

Fig. 1 shows the results of the optimization. The initial airfoil exhibits a strong shock on the upper surface at approximately 55% chord. In the optimized design, this shock is virtually eliminated through a flattened upper surface and increased camber near the trailing edge, resulting in a larger aft-loading characteristic of a supercritical airfoil. The output and parameter history plots show that the minimum drag value is achieved rather quickly, even though the shape and angle of attack keep changing as the load is redistributed on the airfoil. This occurs because after the first few optimization iterations, the remaining shock is weak and its contribution to the drag is small.

4. Field inversion

4.1. Unsteady solution averaging

Let $\bar{\bf U}$ be a statistically-steady flow state computed as the time-average of the unsteady simulation after initial transients,

$$\bar{\mathbf{U}} = \frac{1}{T_f - T_i} \int_{T_i}^{T_f} \mathbf{U}(t) \, dt, \tag{18}$$

where T_i is the start time, taken sufficiently large to minimize startup transient effects, and T_f is the final time, taken sufficiently greater than T_i to yield an adequate statistical mean. The goal of field inversion is to determine a correction field, which enters into the governing equations at the PDE level, to a steady-state model such that the corrected steady-state solution reproduces $\bar{\mathbf{U}}$.

The proximity of the corrected solution to $\bar{\mathbf{U}}$ is measured by the field-inversion error, \mathcal{E} , which could be the error in an engineering quantity such as lift or drag, a weighted combination of errors in scalar quantities, an L_2 norm of the entire state error, an L_2 norm of a surface stress distribution error, etc. Presently, we consider the stress distribution error,

$$\mathcal{E} = \frac{1}{2} \int_{\text{airfoil}} \|\boldsymbol{\sigma}(\mathbf{U}) \cdot \vec{n} - \boldsymbol{\sigma}(\bar{\mathbf{U}}) \cdot \vec{n}\|^2 ds, \tag{19}$$

where σ is the stress tensor and \vec{n} is the unit normal vector on the airfoil surface. We note that the entire time-averaged flowfield is available and could also be used in the error definition. However, by focusing on the surface stress distribution, we have observed better matching of force outputs and their sensitivities.

4.2. Correction-field inversion

In this work, the correction is a scalar field, $\beta(\vec{x})$, that multiplies the production term of the SA turbulence model. The nominal value of this correction field is $\beta=1$. The discrete representation of this field depends on the discretization, and in this work, $\beta(\vec{x})$ is approximated by a p=1 Lagrange DG basis on each element, even for p>1 state approximations. Higher approximation orders for $\beta(\vec{x})$ were found to increase the size of the inverse problem without significantly improving accuracy. Let β be the vector of basis coefficients used in the approximation of $\beta(\vec{x})$, numbering β and β and β and β and β a vector of all ones. The field inversion then becomes a discrete optimization problem,

$$\min_{\boldsymbol{\beta}} \quad J^{\text{inv}} \equiv \mathcal{E}(\mathbf{U}(\boldsymbol{\beta})) + \frac{\gamma}{2} (\boldsymbol{\beta} - 1)^T \mathbf{M} (\boldsymbol{\beta} - 1)
\text{s.t.} \quad \mathbf{R}(\mathbf{U}, \boldsymbol{\beta}) = \mathbf{0}$$
(20)

We have dropped the dependence of the residual on ${\bf x}$, as the design and trim parameters remain fixed during inversion. The additional term in the minimization problem is a continuous Tikhonov regularization that makes the inverse problem well-posed by penalizing large deviations of the correction field from the nominal value of one. ${\bf M}$ is the mass matrix from the spatial discretization, and γ is a small user-prescribed parameter that needs to be sufficiently large to prevent ill-conditioning but not too large so as to affect the minimization of ${\cal E}$. A broad range of values was typically found to be acceptable, and for the normalized problems considered here, with ${\cal O}(1)$ units, $\gamma=10^{-7}$ was used.

To solve (20), we use a simple steepest descent minimization algorithm, in which the PDE-constrained gradient of the objective, J^{inv} , with respect to β is evaluated using an adjoint,

$$\frac{dJ^{\text{inv}}}{d\boldsymbol{\beta}} = \left(\boldsymbol{\Psi}^{\mathcal{E}}\right)^{T} \frac{\partial \mathbf{R}}{\partial \boldsymbol{\beta}} + \gamma \mathbf{M}(\boldsymbol{\beta} - 1), \qquad \left(\frac{\partial \mathbf{R}}{\partial \mathbf{U}}\right)^{T} \boldsymbol{\Psi}^{\mathcal{E}} + \left(\frac{\partial \mathcal{E}}{\partial \mathbf{U}}\right)^{T} = \mathbf{0}. \tag{21}$$

The linearization of the residual with respect to the correction, $\frac{\partial \mathbf{R}}{\partial \boldsymbol{\beta}}$, is local to the elements: by virtue of the DG discretization and the fact that the correction enters via a residual source term, coefficients of $\boldsymbol{\beta}$ for an element affect the discrete residuals only on that element. Therefore, in this work, $\frac{\partial \mathbf{R}}{\partial \boldsymbol{\beta}}$ is evaluated efficiently using finite differences. This requires only a small number of residual evaluations (e.g. 3 for triangles), as derivatives on all elements can be calculated concurrently.

4.3. Example

To demonstrate the accuracy of the RANS correction, we consider a NACA 3412 airfoil at M=0.2, $Re=10^4$, and angle of attack $\alpha=0$. This low Reynolds-number flow exhibits unsteady behavior that prevents the use of direct unsteady adjoints for time-averaged outputs [59]. The case is solved using p=2 solution approximation on a mesh of 1978 q=3 quadrilateral elements. A third-order modified backwards difference scheme (MEBDF) [52] is used to advance the unsteady cases in time, using a time step of $\Delta t=.05c/U_{\infty}$, where U_{∞} is the free-stream speed. After a transient, a time horizon of $T_f-T_i=30c/U_{\infty}$ is used to calculate the average state according to (18).

RANS models are typically tuned for high Reynolds-number turbulent flows, so we should not expect good agreement between unsteady results and a standard RANS result. This is indeed the case, as shown in Fig. 2. The uncorrected RANS solution exhibits a smaller wake and a different pressure distribution compared to the averaged unsteady result. With the correction to the production term, however, the RANS model can be modified to quite-well match the averaged unsteady result. Fig. 2 shows that the Mach number profile and pressure distribution of the corrected RANS result are nearly identical to the time-averaged unsteady result. The field inversion in this case is done using the stress distribution error function, (19). The $\beta(\vec{x})$ plot indicates reduced turbulent production on the boundary layer edges, particularly over the upper surface, and increased production towards the trailing edge and wake.

5. Machine learning

5.1. Overview

The correction field obtained from the solution of the inverse problem presented in Section 4 makes the solution of the corrected RANS equations match the unsteady average for a particular geometry and mesh. In design optimization, we would like to consider changes to the geometry and trim parameters, which lead to different meshes and states. The correction field then also needs to change, in a manner generally beyond a simple mapping, as new geometry or state features may require local changes to the correction.

One approach to realizing consistent changes to the correction field is to make this field a function of the state and gradient, i.e. to create a model for β as a function of the *local* \mathbf{u} and $\nabla \mathbf{u}$. As the correction enters the equations at the residual level, propagation effects of convection-dominated systems can be modeled in this approach. For example, a discrepancy in the location of separation can be resolved through changes in the turbulent production at/before separation, where the boundary-layer profile can be controlled, instead of in the wake, where the largest state discrepancies occur but where little control is possible.

The link between the state and the correction field can be made in the form of an analytical model [60], where the coefficients of the model can be fit to features of the state. Alternatively, the analytical model can be replaced altogether by a direct mapping from the state to the correction field, through an artificial neural network [61,62]. This idea forms the basis of the field-inversion machine-learning

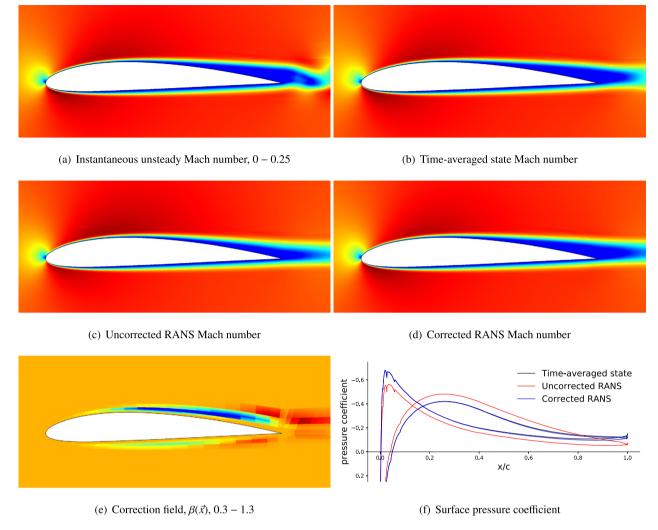

Fig. 2. Field-inversion results for unsteady flow around a NACA 3412 airfoil at M=0.2, $Re=10^4$, $\alpha=0$.

(FIML) approach to corrected turbulence modeling [27]. We note that the network plays a minor role in this method, in contrast to other approaches that use a network to replace the entire turbulence model [63]. In FIML, the network could be replaced by other functional mappings or closed form expressions [33].

FIML has seen success in making solutions of corrected turbulence models match unsteady or higher-fidelity data for a variety of cases [28,30,31,33]. The generality of this approach is still in debate [26], and it is possible that FIML may never yield a general-purpose "new" turbulence model that performs better than existing analytical ones. In addition, the identification and selection of the most physically relevant local state features for use as inputs into the neural network has a high degree of arbitrariness [31].

These possible shortcomings of FIML do not affect our present work, which does not aim to derive a general-purpose turbulence model. Our goal is to create a locally-valid corrected turbulence model that reproduces the behavior of the unsteady system at geometries and conditions that are close in parameter space. The model is retrained as the optimization progresses and more unsteady data become available. Furthermore, the fact that the model is specific to the problem simplifies the network input selection. Instead of choosing, perhaps arbitrarily, non-dimensional, physically meaningful features, we take a more systematic approach and use the entire state vector, its spatial gradient, and the wall distance as the network input.

5.2. Network architecture and training

The neural network maps local flowfield information to the scalar correction field. Fig. 3 shows the structure of the network used in this work, which is a single-hidden-layer perceptron. The hidden layer, \mathbf{x}_1 , contains n_1 neurons, between the input layer, i.e. the features, \mathbf{x}_0 , and the output layer, which consists of the scalar correction factor, β . The map from the input to the hidden layer involves an entry-wise sigmoid activation function, $\sigma(x) = 1/(1 + e^{-x})$, whereas no activation function is used for the output layer calculation. The parameters associated with the network consist of the weights and biases, $\mathbf{W}_i \in \mathbb{R}^{n_i \times n_{i-1}}$, $\mathbf{b}_i \in \mathbb{R}^{n_i}$, where n_i is the number of neurons in layer i.

The input into the network consists of the state, \mathbf{u} , its gradient, $\nabla \mathbf{u}$, and the wall distance, d, for a total of $(1 + \dim)s + 1$ neurons. After experimentation, the size of the hidden layer was set to $n_1 = 30$ for the two-dimensional problems considered here. The observed trade-off lies between over-fitting and high quadrature order requirements for large n_1 and a loss of accuracy for small n_1 . A fairly wide range of values, $n_1 \in [16, 50]$, showed similar performance, so that the results are not overly sensitive to the precise value of n_1 .

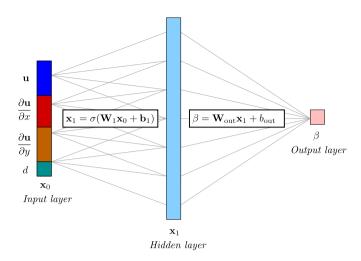

Fig. 3. Structure of the artificial neural networks used to predict the correction field.

The parameters associated with the network consist of all of the weights and biases. The values of these parameters are determined using an optimization procedure, the adaptive moment (Adam) estimation algorithm in TensorFlow [64], that minimizes the mean squared error loss function between predicted and actual output-layer values. The actual output-layer values, i.e. values of the correction field, come from the field inversion result for one particular unsteady simulation. As $\beta(x)$ is a field, each simulation yields ostensibly an infinite amount of training data. However, the finite-dimensional representation of the state and $\beta(x)$ means that not all of these data are independent or informative for training. In the present work, we sample the required fields (state, gradient, wall distance, correction) at the quadrature points of each element. Each inversion result then yields an amount of training data that depends on the mesh size and quadrature order.

The training data are broken into mini-batches of size 1000 for the optimizer, and the learning rate is set to .001. Prior to training, the weights and biases are initialized randomly from a unit normal distribution. Experiments with different learning rates, batch sizes, and initialization showed that the final results were not overly sensitive to these choices. 500,000 optimization iterations are taken in each training session for all of the presented results, although the mean-squared error typically stabilizes well before this number. Two to three orders of magnitude drop in the loss are usually observed.

5.3. Implementation and example

Once a network is trained, it is implemented as a physics model in the turbulence source calculation of the flow simulation code. No changes to the inputs to this calculation are required, since the turbulent source already uses the state, its gradient, and the wall distance function. All parts of the source calculation must be differentiated with respect to the state and its gradient for the forward Newton solver and the discrete adjoint solver. This includes the neural-network correction field calculation, the linearization of which is calculated using back-propagation [61]. For a single-hidden layer network, the derivative of the scalar output with respect to the input vector is calculated as follows:

$$\beta = \mathbf{W}_{\text{out}}\sigma(\mathbf{W}_{1}\mathbf{x}_{0} + \mathbf{b}_{1}) + b_{\text{out}} \quad \Rightarrow \quad \frac{\partial \beta}{\partial \mathbf{x}_{0}} = \mathbf{W}_{2} \operatorname{diag}(\sigma'_{1}) \mathbf{W}_{1}, \tag{22}$$

where σ'_1 is the derivative of the activation function at the hidden layer values. For the sigmoid function, this derivative is $\sigma' = \sigma(1 - \sigma)$, and hence its calculation only requires storing the hidden layer post-activation values. The chain rule calculation in (22) extends systematically to multiple hidden layers. Due to the nonlinear nature of the network, higher-order accurate quadrature rules are used for the corrected RANS model. Presently, an constant order increment of 1 is added to the baseline 2p + 1 order requirement in the code.

To demonstrate the ability of the neural-network model to produce an accurate correction field, we extend the example in Section 4.3 to multiple airfoils of varying camber. For five airfoils of cambers 0 to 5% of the chord, unsteady simulations, field inversions, and neural network trainings are separately performed. The output of interest is the lift coefficient and its sensitivity to camber changes.

Fig. 4 shows the lift-coefficient results of the various simulations. The uncorrected RANS results show an increasing lift coefficient with camber, and adjoint-based gradients that match the trend from the multiple simulations. However, this trend disagrees with the time-averaged unsteady results, which show an initial decrease in the averaged lift coefficient for small cambers, followed by an increase. The result is not surprising, as the RANS model is not designed for such low Reynolds numbers.

Applying field inversion to each case and using the resulting correction field $\beta(\vec{x})$ in the turbulence model yields data that track the time-averaged results well. More importantly, the neural-network model for $\beta(\vec{x})$ also performs very well, as indicated by the "FIML" data points in Fig. 4. These data correspond to simulations performed by using the neural network model and not the inverted $\beta(\vec{x})$ field, which was used only for training. Furthermore, when differentiated as part of the adjoint solver, the FIML result yields a reasonably-accurate PDE-constrained gradient of the lift coefficient with respect to the camber. The ability to accurately predict the lift coefficient value and its gradient with respect to shape parameters is important when using the FIML correction model in optimization.

Fig. 5 shows the differences in the lift adjoint fields, the conservation of y momentum component, obtained from the uncorrected RANS and the FIML solutions. These are shown on the same scale, and the differences are large, particularly over the upper surface of the airfoil. The correction field, $\beta(\vec{x})$, is also shown, calculated using the neural network at the converged FIML state. This field matches well

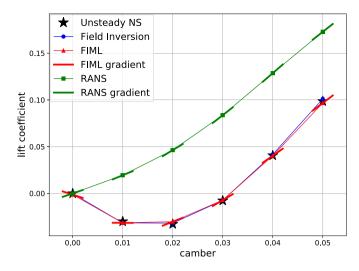

Fig. 4. Field-inversion and machine learning results for lift-coefficient calculations in unsteady flow around NACA X412 airfoils at M=0.2, $Re=10^4$, $\alpha=0$.

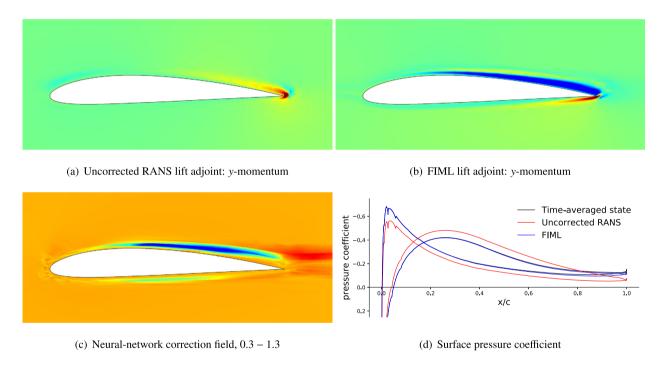

Fig. 5. FIML and RANS contour plots for unsteady flow around a NACA 3412 airfoil at M = 0.2, $Re = 10^4$, $\alpha = 0$.

with the inversion result shown in Fig. 2. Finally, the pressure distribution from the FIML state matches the averaged unsteady pressude distribution just as well as the field inversion result.

6. Unsteady optimization

The objective of the unsteady optimization problem is to determine the airfoil shape that minimizes a given time-averaged cost function, possibly subject to certain constraints. For example, we may be interested in minimizing the time-averaged drag coefficient subject to a fixed time-averaged lift coefficient and geometrical constraints such as airfoil area and minimum thickness. Our chosen airfoil parametrization automatically enforces shape constraints of the latter form, and output constraints are handled via concurrent trimming.

In trimmed simulations, the trim conditions are enforced in steady mode prior to and then concurrently with the optimization, as described in Section 3.1. In unsteady mode, trimming with one parameter is performed by averaging the trimming output (e.g. lift coefficient) over a prescribed time range and adjusting the trim parameter (e.g. angle of attack) at discrete intervals to achieve the target output. The sensitivities required for the parameter change are computed from a finite-difference of the previous two output and parameter values. The initial sensitivity comes from an adjoint-based derivative about the average state. A prescribed "burn" window, during which no averaging is performed, follows each parameter change and the initial time. Fig. 6 summarizes this unsteady trimming procedure.

The proposed unsteady optimization approach consists of the following steps:

1. Run the unsteady simulation, with trimming if needed, and save the average state.

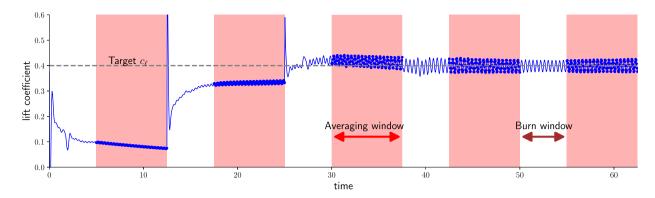

Fig. 6. Unsteady trimming of the lift coefficient using the angle of attack, taken from a simulation of the airfoil studied in Section 7.1.

- 2. Perform field inversion using the RANS model at the same geometry and free-stream conditions to determine the correction field, $\beta(\vec{x})$.
- 3. Train the neural network model to compute the correction as a function of the state, gradient, and wall distance, $\beta(\vec{x}) \to \beta(\mathbf{u}, \nabla \mathbf{u}, d)$.
- 4. Optimize the geometry in steady mode using the correction model, i.e. FIML.
- 5. Return to step 1.

Each cycle through these steps constitutes an unsteady optimization iteration. The initial airfoil shape for the first unsteady simulation could be based on default parameters or it could be the result of a steady-state optimization. The latter is generally more efficient, although we present both approaches in the results.

7. Results

This section presents a sequence of three numerical results that demonstrate the unsteady optimization method introduced in this work. The computational meshes in each case consist of q=3 curved quadrilaterals generated by a script according to the specified shape parameters. Anisotropic elements resolve the boundary layer through a non-uniform airfoil-normal spacing chosen a priori based on the Reynolds number. Fig. 7 shows the meshes, at the optimized geometries, for the three cases considered. The angle of attack is imposed through a static arbitrary Lagrangian-Eulerian pitch deformation centered at the airfoil mid-chord and blended to zero 20 airfoil chord lengths away from the center.

7.1. Fixed-lift drag minimization, $Re = 10^4$

As a first example, we consider a drag minimization problem for an airfoil at a prescribed lift coefficient of $c_{\ell} = 0.4$, and M = 0.2, $Re = 10^4$. No turbulence model is used in the unsteady simulations at this low Reynolds number. The area of the airfoil is constrained to $A = .06c^2$ via (17). Three camber parameters, c_0 , c_1 , c_2 in (14), and two thickness parameters, t_1 , t_2 in (15), dictate the shape of the airfoil. All five of these parameters are set to zero to obtain the initial shape.

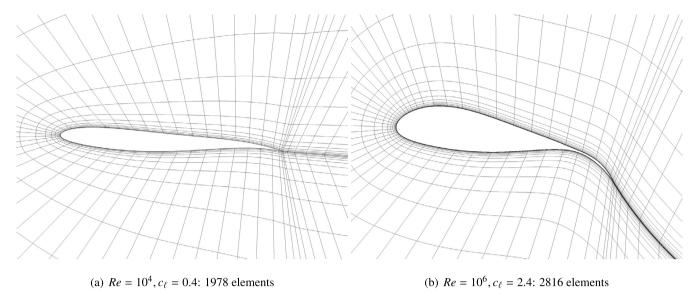

In this case, we first trim the initial airfoil in unsteady mode to determine the lift coefficient that attains the prescribed average lift coefficient. Fig. 8(a) shows the lift coefficient time history for a portion of the trimmed condition, along with a snapshot of the x-momentum contour field. The initial airfoil exhibits large oscillations in the lift coefficient, in the approximate range $c_{\ell} \in [0.2, 0.6]$ and frequency of $1c/U_{\infty}$, where U_{∞} is the freestream speed.

The oscillatory flowfield and outputs prevent the application of standard unsteady adjoint techniques for computing gradients [65, 66,59]. Fig. 9 shows the backward-in-time growth of the adjoint solution norm for a time-integral lift output, along with snapshots of the instantaneous adjoint. In addition to this instability, a full unsteady adjoint solution is also expensive in storage and computational overhead of the reverse time-marching solution, rendering it impractical for unsteady turbulent flows. We stress that the present approach does not require unsteady adjoints, as it creates a tailored steady-state model for the time-averaged solution and optimizes using this model.

The time-averaged state and outputs for the initial airfoil were obtained using $20c/U_{\infty}$ time units of the trimmed unsteady simulation. The average values were used as targets in the field inversion process, as described in Section 4. In particular, 50 steepest-descent iterations were taken to determine the $\beta(\vec{x})$ field that minimized the error in the airfoil surface stress distribution. Fig. 8(b) show the resulting correction field and x-momentum contours from the corrected RANS simulation. Note that the correction field calls for a general decrease of turbulent production at the edge of the upper-surface boundary layer, which leads to earlier separation and higher drag compared to an uncorrected-RANS simulation.

Data from this correction field were used to train a neural network, with one hidden layer of 30 neurons, to predict β from the local state, gradient, and wall-distance function. The RANS equations together with the network-based correction field constitute the FIML model, which is used in a steady shape optimization. Fig. 8(c) shows the result of 50 BFGS optimization iterations using this first FIML model. The optimized shape exhibits a reduced suction peak, a higher aft-loading redistribution of the lift, and a shift of area from the aft the front of the airfoil.

The combination of unsteady simulation, field inversion, and corrected steady optimization constitutes one *FIML optimization iteration*. This process is repeated with the optimized airfoil, and Fig. 10 shows the results of the second FIML optimization iteration, which parallel those of Fig. 8.

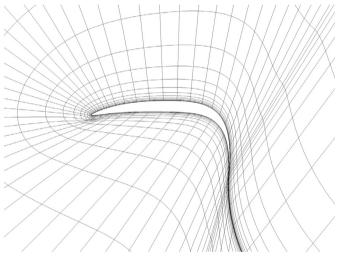

Fig. 7. Meshes used in the three results cases, shown for the final optimized geometries.

(c) $Re = 10^4$, max (c_ℓ) : 2112 elements

The flowfield remains unsteady for the optimized airfoil, but the unsteady trimming time history in Fig. 10(a) shows a reduced amplitude of the lift coefficient variation, by almost a factor of two compared to Fig. 8(a). Field inversion was then performed using the time-averaged surface stress distribution as a target and the same parameters as in the first iteration. Fig. 10(b) shows the resulting correction field and x-momentum contours. The dominant feature of the correction field is again a suppression of turbulent production on the upper surface. A similar but lower-magnitude suppression now also appears on the lower surface due to the adverse pressure gradient brought about by the increased aft camber.

A new neural network is constructed from the second correction field, and the resulting FIML model is used to re-optimize the airfoil shape. Fig. 10(c) shows the shape and pressure distribution of the second FIML optimization iteration. The changes in the shape compared to the first FIML optimization are not large: a slight flattening of the upper surface and reduction in overall camber, except for the aft portion.

Two additional FIML optimizations were performed, each with a separate unsteady simulation, inversion, and steady optimization. Fig. 11 shows the final FIML-optimized airfoil shape, along with a comparison to the uncorrected-RANS optimization result. The latter shape, referred to simply as the RANS airfoil, exhibits a rounder upper surface and a more aggressive thickness decrease along the chord, which leads to a larger-magnitude adverse pressure gradient. An uncorrected RANS analysis of this airfoil yields the Mach number contours shown in Fig. 11(b): the flow remains attached on the upper and lower surfaces. However, an unsteady analysis without the RANS model results in a different picture. Fig. 11(c) shows the Mach number from the time-averaged state, and the wake is much larger due to separated flow on the upper surface. In contrast, the FIML-optimized airfoil yields a time-averaged state with a smaller wake due to, on average, later separation enabled by a less adverse pressure gradient.

Table 1 summarizes the optimization results in terms of the average drag coefficient from a trimmed unsteady simulation of the various airfoils. RANS-alone optimization yields a drag reduction by almost 50 counts compared to the chosen initial airfoil. This is similar to the result from the first iteration of the FIML optimization. However, subsequent FIML optimizations further reduce the average drag by over 40 drag counts.

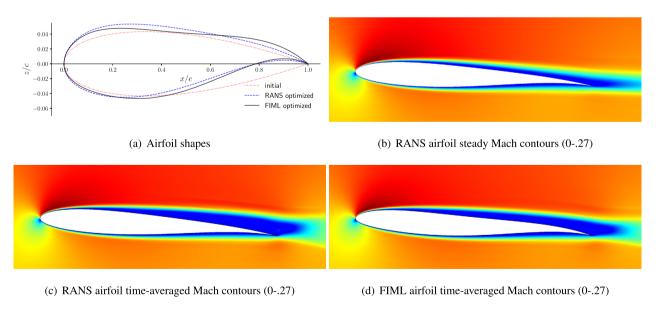

Fig. 11. Comparison of RANS and FIML optimized airfoil shapes and time-averaged Mach number contours at M=0.2, $Re=10^4$, $c_\ell=0.4$.

To verify the importance of the correction model on the optimal shape, the final FIML-optimized airfoil was used as the initial airfoil in an uncorrected-RANS optimization. The result of this optimization was the same RANS-alone optimized result obtained from the original initial airfoil, shown in Fig. 11. This indicates that the FIML correction-field model is responsible for the additional over 40 counts of drag reduction compared to an uncorrected RANS optimization.

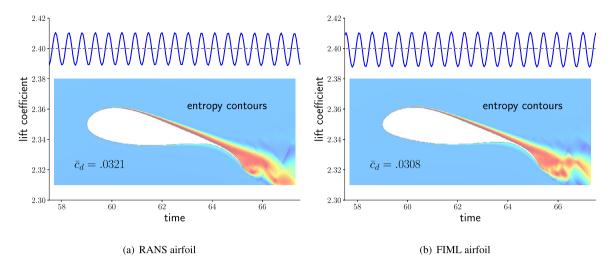

Fig. 12. Unsteady analyses of RANS and FIML airfoils optimized for minimizing drag at M = 0.2, $Re = 10^6$, $c_\ell = 2.4$.

RANS airfoil, unsteady analysis	0.0321
FIML airfoil, unsteady analysis	0.0308

7.2. Fixed-lift drag minimization, $Re = 10^6$

We next consider a drag minimization problem at a higher lift coefficient, $c_{\ell} = 2.4$ and Reynolds number, $Re = 10^6$. The free-stream Mach number remains M = 0.2, but the airfoil is thicker, with area constrained to $A = 0.1c^2$. Four camber parameters, c_0 , c_1 , c_2 , c_4 in (14), and three thickness parameters, t_1 , t_2 , t_3 in (15), dictate the shape of the airfoil.

In this case, we first optimize the airfoil using the standard, uncorrected RANS equations. The resulting shape, termed the RANS airfoil, is then trimmed in unsteady mode, using the simple DES model described in Section 2.1, with $d_{\text{max}} = .02c$. The time-averaged state and output from the trimmed unsteady simulation provide the target data for field inversion, machine learning, and the follow-up FIML optimization. We refer to the resulting airfoil as the FIML airfoil, and we compare its performance to that of the RANS airfoil.

Fig. 12 shows the unsteady lift coefficient time histories, after trimming, of both the RANS and the FIML airfoils. These are similar and exhibit small variations about the target mean. The flow develops unsteadiness in the wake of the upper surface, as shown by the accompanying entropy contours.

The optimized airfoil shapes, shown more clearly in the subsequent figures, exhibit a couple of interesting features. First, the aft portion of the airfoil is very thin. The thickness constraint is active, as most of the required airfoil area is placed towards the front of the airfoil. The aft portion is also highly cambered, and thus responsible for much of the lift generation as well as the unsteadiness due to separation. However, as this is a small region, the resulting unsteadiness does not dominate the flowfield the flow remains attached over the majority of the airfoil.

Fig. 13(a) compares the RANS and FIML airfoil shapes. We see that the shapes are quite similar, with the FIML airfoil redistributing some of the thickness from the front of the airfoil over a larger portion of the chord. The FIML airfoil also has a slightly sharper leading edge. The correction field obtained after field inversion, shown in Fig. 13(b), shows a thin region of suppression of turbulence production over the upper surface, which is responsible for boundary layer thickening and an earlier point of separation. The correction is largely inactive over the lower surface but flares up in the wake, shortly behind the trailing edge, in the form of a confined region of suppression of turbulent production. This suppression reduces mixing in the shear layer between the lower and upper surface flows.

Finally, Fig. 13 also shows the Mach number contours from both the steady and the time-averaged unsteady flowfields of the RANS and FIML airfoils, respectively. The high Reynolds number of this flow makes the differences difficult to discern, but both the upper-surface boundary layer and the wake are thicker in the time-averaged FIML-airfoil case than in the steady RANS airfoil case. These differences impact the outputs: the steady RANS analysis predicts a drag coefficient that is 46 counts lower than the time-averaged result.

Table 2 summarizes the drag coefficient results for the two airfoils. The RANS airfoil is a result of a steady optimization using the standard RANS equations. It is analyzed both in steady and unsteady, DES, modes. The first two lines of Table 2 show the differences in the trimmed-state drag coefficients between these two analyses of the RANS airfoil: 45 counts higher for the unsteady analysis. The time-averaged unsteady analysis of the RANS airfoil provides the target data for the field inversion and training of the FIML model, an optimization of which yields the FIML airfoil. The parametrization remains the same: seven shape parameters and the angle of attack as the trim parameter. The last line of Table 2 shows the unsteady-analysis drag coefficient result for the FIML airfoil: a reduction of 13 drag counts relative to the RANS airfoil. As in the previous case, the shape difference between the two airfoils was tested for persistence: an uncorrected RANS optimization starting with the FIML airfoil reverts back to the RANS airfoil.

Although the primal flowfields of the RANS and FIML airfoils are similar, differences in the adjoint solutions are more pronounced. Fig. 14 compares the drag adjoints obtained from the uncorrected RANS equations and the RANS equations with the FIML correction, referred to as the FIML equations. Both fields are shown on the same shape, the RANS airfoil, and the adjoint component shown corresponds

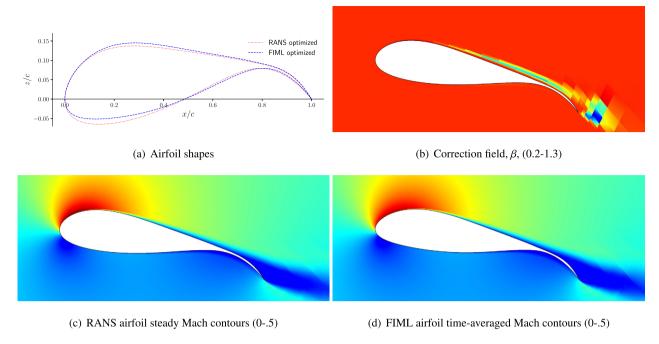

Fig. 13. Comparison of RANS and FIML airfoil shapes, the correction field, and Mach number contours for drag minimization at M=0.2, $Re=10^6$, $c_\ell=2.4$.

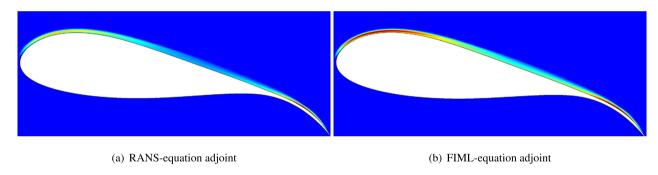

Fig. 14. Field plots of the conservation of *x*-momentum component of the drag adjoint for the RANS-optimized airfoil, using both the RANS equations and the corrected, FIML equations at M = 0.2, $Re = 10^6$, $c_\ell = 2.4$.

to the conservation of *x*-momentum equation. We see that for the FIML equations, the drag is more sensitive to residual perturbations along the upper surface, close to the airfoil, particularly in the acceleration region over the front of the airfoil and the high-camber aft portion. These differences in the adjoint arise from differences in both the primal state and the residual Jacobian matrix. The latter is caused by the linearization of the neural-network model for the correction field, which affects the matrix of the adjoint linear system.

7.3. Lift maximization, $Re = 10^4$

As a final example, we consider the maximization of the lift produced by an airfoil at free-stream M = 0.2 and $Re = 10^4$. The airfoil has an area constraint of $A = 0.06c^2$, and the design parameters consist of the same seven shape parameters as in the previous example, Section 7.2, augmented by the angle of attack. No trim parameters are necessary for this unconstrained maximization problem.

As in the previous example, we first optimize the airfoil using the uncorrected RANS equations, starting from a baseline airfoil in which all shape parameters are zero, and this optimization yields the RANS airfoil. An unsteady analysis of the RANS airfoil is then performed, and time-averaged state and output information from the unsteady analysis of the RANS airfoil provide the target data for field inversion and machine learning. The resulting FIML model is used to re-optimize the airfoil with unsteady information, using the same optimization technique as for the steady RANS case. The combination of unsteady analysis and FIML optimization constitutes one FIML optimization iteration, and a total of three such iterations (requiring three unsteady analyses) are performed to obtain the FIML airfoil. We note that the RANS and the FIML airfoils also each come with their optimized angle of attack.

Fig. 15 shows the geometries of the two airfoils. Both are highly cambered, with a smooth, near right-angle flow deflection at the trailing edge, starting at approximately 75% of the chord. However, the airfoils do have noticeable differences. The FIML airfoil has a smaller radius of curvature at the leading edge and is thinner for the first 25% of the chord. Its thickness then gradually increases over the middle before tapering off at the trailing edge. In contrast, the RANS airfoil starts out thicker and maintains a relatively constant thickness distribution from 25% to 70% of the chord. Its upper surface is also flatter than that of the FIML airfoil. The optimum angles of attack for the two airfoils are not too different: 22.92° for the RANS airfoil and 23.41° for the FIML airfoil. These large values align the flow with the direction of the first portion of the airfoil, so that the last 25% of the chord constitutes an effective smooth flap.

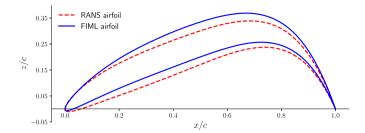

Fig. 15. Airfoils optimized for maximum lift at M = 0.2, $Re = 10^4$.

Table 3 Lift coefficient results for lift maximization at M = 0.2, $Re = 10^4$.

Airfoil	Angle of attack	Analysis	Lift coefficient
RANS airfoil	22.92°	Steady	1.93
RANS airfoil	22.92°	Unsteady	2.71
FIML airfoil	23.41°	Steady	1.85
FIML airfoil	23.41°	Unsteady	2.94

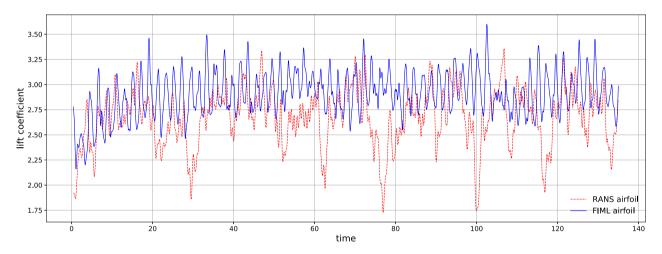

Fig. 16. Lift coefficient time histories for lift maximization at M = 0.2, $Re = 10^4$.

Table 3 presents the lift coefficient results for the optimized airfoils. It shows values from a steady-state RANS analysis and an unsteady analysis (time-averaged value), for both airfoils. Simulations for each airfoil are performed at the airfoil's optimized angle of attack. We see that each airfoil has the higher lift coefficient in the analysis that matches the optimization. The RANS airfoil has the higher lift coefficient in the steady analysis, as expected from the steady optimization. The FIML airfoil has the higher lift coefficient in the unsteady analysis, by over 8.5%, which indicates that the FIML model is accounting for the unsteady effects of the flow. We also note that the unsteady analyses predict much higher lift coefficients than steady RANS, by 40% to 60%.

Fig. 16 shows the lift coefficient time histories from the unsteady analyses of the two airfoils. Both histories show a high degree of unsteadiness, but the range of lift coefficient variation is smaller in the FIML airfoil case: between 2.5 and 3.5 compared to 1.75 and 3.25 in the RANS airfoil. The time history of the RANS airfoil lift coefficient is punctuated by large drops in the lift coefficient, which correspond to large vortex shedding events off the leading edge. These are not present for the FIML airfoil. In addition, the overall lower average lift coefficient for the RANS airfoil is discernible from the time histories.

Fig. 17 compares Mach number snapshots of the unsteady flowfields for both airfoils. The large degree of unsteadiness in the flowfield is apparent, with vortices that start shortly after the leading edge on the upper surface. The flat front portion of the RANS airfoil leads to a larger region of leading-edge separation, in contrast to the more cambered FIML airfoil front portion that allows for reattachment. In both airfoils, the high effective flap angle leads to large shed vortices in the wake.

Fig. 18 shows the time-averaged Mach number contours for both cases, computed from the unsteady analyses. We see that a region of separated flow on the upper surface starts almost immediately at the leading edge in both airfoils, but that it re-attaches by the start of the flap in the FIML airfoil. This then leads to more flow turning on the upper surface and hence larger lift generation. In the RANS airfoil case, the flow does not re-attach, leading to a larger wake, less flow turning and hence less lift.

Finally, to test the performance of the airfoils off-design, and to verify the angles of attack determined from the optimization, we perform an angle of attack sweep of both airfoils. For the unsteady analyses, this involves running a separate unsteady simulation at each angle of attack and computing the time-averaged lift coefficient. Fig. 19 shows the resulting lift coefficient curves. In addition to the two unsteady analyses, we also include a steady analysis result of the RANS airfoil. The optimal angles of attack for the unsteady FIML airfoil analysis and the steady RANS airfoil analysis are indeed correctly predicted by the optimization, as indicated by the large symbols. The unsteady angle of attack sweep of the RANS airfoil shows that the maximum time-averaged lift actually occurs at an angle of attack that

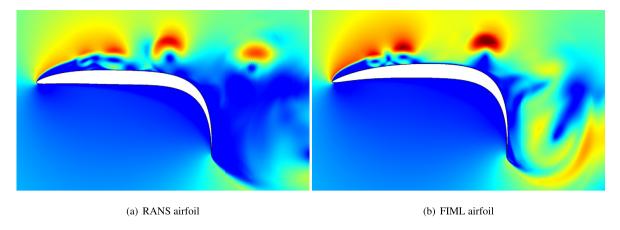

Fig. 17. Instantaneous Mach number contours (0-.5) of airfoils optimized for lift maximization at M = 0.2, $Re = 10^4$.

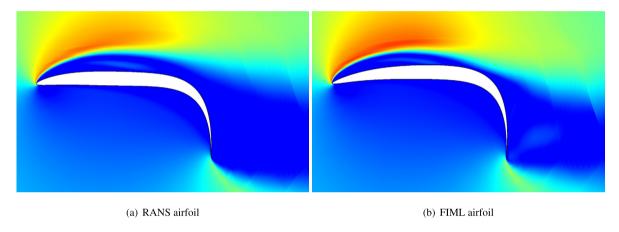

Fig. 18. Time-averaged Mach number contours (0-.5) of airfoils optimized for lift maximization at M = 0.2, $Re = 10^4$.

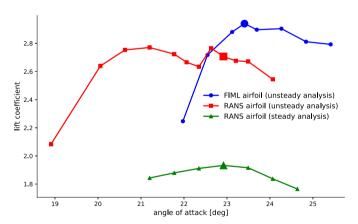

Fig. 19. Lift coefficient versus angle of attack for the optimized airfoils for lift maximization at M = 0.2, $Re = 10^4$. Large symbols indicate the angle of attack determined from the optimization.

is lower, about $\alpha = 21^{\circ}$, than the 22.92° angle predicted by the steady analysis. In contrast, the FIML optimization correctly predicts the angle of attack at maximum time-averaged lift.

8. Summary and discussion

8.1. Methods summary

This paper introduces a gradient-based approach for optimizing shapes of airfoils in unsteady turbulent flows. The most challenging aspect of this problem is the calculation of the gradient, which is the sensitivity of the output with respect to the shape parameters. Whereas adjoint-based methods enable efficient gradient calculations, their application to unsteady turbulent flows is hampered by the fact that for problems exhibiting chaotic or limit-cycle oscillations, a direct unsteady adjoint solution is unstable. Furthermore, unsteady

adjoint solutions are inherently expensive, becoming impractical for large simulations in which only a few forward primal solutions can be afforded

The gradient calculation proposed in this work does not rely on an unsteady adjoint. Instead, a steady-state model is first created from the unsteady simulation data, and the adjoint method is applied to the steady-state model. The steady-state model is based on the Reynolds-averaged Navier-Stokes equations, to which a correction is applied via a multiplicative factor on the production term. The correction factor is a field quantity that is computed from the unsteady simulation data by solving an inverse problem. The unsteady simulation provides the target data for this inversion.

Following the field inversion, a neural network model is trained to produce the correction factor from local flow data. The single corrected RANS solution provides a large quantity of training data, as the correction factor is measured at the quadrature points of each element. The local data consist simply of the state, its spatial gradient, and the wall distance. No effort is made to form non-dimensional inputs, as the network does not need to be generalizable across different flow regimes or vastly-different geometries. Instead, the network is used only for a single steady-state optimization. The network must be linearized for accurate adjoint calculations. After shape and trim parameter changes, a new unsteady run follows, and a new network is trained. Thus, the goal of the machine learning as used in this work is not to create a new turbulence model, but to enable the calculation of an adjoint for an unsteady flow.

The discretization used in this work is a discontinuous Galerkin (DG) finite-element method with implicit time stepping. DG allows for a high-order solution representation that can be more efficient at resolving the smooth unsteady flows considered here, with features at multiple length and time scales. However, the unsteady optimization approach is not tied to DG and could be used with other discretizations, such as finite-volume or finite-difference methods. Similarly, the method is not tied to the unsteady model, which here is the Navier-Stokes equations with a very simple DES at large Reynolds numbers. Indeed, as the method is not intrusive into the unsteady simulation, independent "black-box" unsteady solvers could be used, with various levels of fidelity, including DES or LES. Only average flowfield statistics are required for the inversion and training. Finally, the approach is not tied to the specific steady-state optimization method, as long as it is gradient-based. This work uses the BFGS method with concurrent trimming, and a polynomial-based parametrization of the airfoil camber and thickness. Other, more sophisticated optimization approaches could also be used.

8.2. Discussion and conclusions

The ideal application of the presented unsteady optimization approach is ostensibly to turbulent flows that are unsteady but reasonably well-approximated by the baseline steady turbulence model. However, we have shown cases that span a range of unsteadiness level, from small-scale to massive separation. These include drag minimization and lift maximization, at low and high Reynolds numbers. In all cases, unsteady optimization yields improved designs. For the high Reynolds number case, we observe a drag reduction of over 4% over a standard RANS optimization. This is a modest gain, as RANS is already a decent model for high Reynolds number flows with small-scale unsteadiness.

More interesting is the low-Reynolds number, fixed-lift drag minimization at $Re = 10^4$. In this case, the RANS model by itself is not accurate, as it predicts attached flow whereas the averaged unsteady flowfield has a high propensity for separation. With a correction, primarily suppression of turbulent production, the FIML model is able to very well approximate the averaged unsteady flowfield and outputs. Moreover, the gradients computed from the FIML model also match reasonably well with the unsteady flowfield gradients. As a result, optimization with the FIML model leads to a design that has an 18% lower averaged drag coefficient compared to the RANS optimization, when both are analyzed using the unsteady Navier-Stokes equations.

Pushing the algorithm to a flowfield with even more unsteadiness, we optimize an airfoil at $Re = 10^4$ purely for maximum lift, without regard to drag. Both RANS and FIML airfoil shapes attempt to turn the flow as much as possible in this case, leading to massive separation off the top surface and many vortex shedding events. However, camber and thickness differences in the front portion of the airfoil are responsible for the FIML airfoil exhibiting re-attachment before the beginning of the downward flap deflection, leading to increased flow turning and lift. The improvement is 8.5% over the RANS airfoil in unsteady analysis, whereas the steady RANS analysis severely underpredicts the lift. This result shows that the unsteady optimization approach can be applied to cases in which the original RANS model would not be deemed appropriate. Extending the FIML/RANS combination to more off-design conditions, including bluff bodies, and to multidisciplinary design optimization problems is the subject of future work.
